Foreword

The U.S. Geological Survey (USGS) is committed to providing the Nation with reliable scientific information that helps to enhance and protect the overall quality of life and that facilitates effective management of water, biological, energy, and mineral resources (*http://www.usgs.gov/*). Information on the Nation's water resources is critical to ensuring long-term availability of water that is safe for drinking and recreation and is suitable for industry, irrigation, and fish and wildlife. Population growth and increasing demands for water make the availability of that water, measured in terms of quantity and quality, even more essential to the long-term sustainability of our communities and ecosystems.

The USGS implemented the National Water-Quality Assessment (NAWQA) Program in 1991 to support national, regional, State, and local information needs and decisions related to water-quality management and policy (*http://water.usgs.gov/nawqa*). The NAWQA Program is designed to answer: What is the quality of our Nation's streams and groundwater? How are conditions changing over time? How do natural features and human activities affect the quality of streams and groundwater, and where are those effects most pronounced? By combining information on water chemistry, physical characteristics, stream habitat, and aquatic life, the NAWQA Program aims to provide science-based insights for current and emerging water issues and priorities. From 1991 to 2001, the NAWQA Program completed interdisciplinary assessments and established a baseline understanding of water-quality conditions in 51 of the Nation's river basins and aquifers, referred to as Study Units (*http://water.usgs.gov/nawqa/studies/study_units.html*).

In the second decade of the Program (2001–2012), a major focus is on regional assessments of waterquality conditions and trends. These regional assessments are based on major river basins and principal aquifers, which encompass larger regions of the country than the Study Units. Regional assessments extend the findings in the Study Units by filling critical gaps in characterizing the quality of surface water and groundwater, and by determining water-quality status and trends at sites that have been consistently monitored for more than a decade. In addition, the regional assessments continue to build an understanding of how natural features and human activities affect water quality. Many of the regional assessments employ modeling and other scientific tools, developed on the basis of data collected at individual sites, to help extend knowledge of water quality to unmonitored, yet comparable areas within the regions. The models thereby enhance the value of our existing data and our understanding of the hydrologic system. In addition, the models are useful in evaluating various resource-management scenarios and in predicting how our actions, such as reducing or managing nonpoint and point sources of contamination, land conversion, and altering flow and (or) pumping regimes, are likely to affect water conditions within a region.

Other activities planned during the second decade include continuing national syntheses of information on pesticides, volatile organic compounds (VOCs), nutrients, trace elements, and aquatic ecology; and continuing national topical studies on the fate of agricultural chemicals, effects of urbanization on stream ecosystems, bioaccumulation of mercury in stream ecosystems, effects of nutrient enrichment on stream ecosystems, and transport of contaminants to public-supply wells.

The USGS aims to disseminate credible, timely, and relevant science information to address practical and effective water-resource management and strategies that protect and restore water quality. We hope this NAWQA publication will provide you with insights and information to meet your needs, and will foster increased citizen awareness and involvement in the protection and restoration of our Nation's waters.

The USGS recognizes that a national assessment by a single program cannot address all water-resource issues of interest. External coordination at all levels is critical for cost-effective management, regulation, and conservation of our Nation's water resources. The NAWQA Program, therefore, depends on advice and information from other agencies—Federal, State, regional, interstate, Tribal, and local—as well as nongovernmental organizations, industry, academia, and other stakeholder groups. Your assistance and suggestions are greatly appreciated.

William H. Werkheiser USGS Associate Director for Water

Use of Classes Based on Redox and Groundwater Age to Characterize the Susceptibility of Principal Aquifers to Changes in Nitrate Concentrations, 1991 to 2010

By P.B. McMahon

Abstract

The National Water-Quality Assessment (NAWQA) Program of the U.S. Geological Survey is using multiple approaches to measure and explain trends in concentrations of nitrate in principal aquifers of the United States. Near decadal sampling of selected well networks is providing information on where long-term changes in nitrate concentrations have occurred. Because those studies do not include all the NAWQA well networks, a determination has yet to be made as to what might be expected in networks from which timeseries data have not been collected. Characterizing aquifer susceptibility to changes in nitrate concentrations on the basis of data collected from all the NAWQA well networks would be a step toward extrapolating findings from those studies to broader regions.

In this study, water samples collected from 6,593 wells in 39 principal aquifers and 5 alluvial aquifers (collected from 1991 to 2010) were assigned to four redox-age classes on the basis of concentrations of dissolved oxygen and various indicators of groundwater age. The redox-age assignments were then used to characterize the susceptibility of principal aquifers to changes in nitrate concentrations. Aquifer areas (as defined by well networks) in which at least 75 percent of the samples were classified as oxic-potentially young were considered to have a high susceptibility to changes in nitrate concentrations. Aquifer areas were considered to have a medium susceptibility if at least 25 percent and less than 75 percent of the samples were classified as oxicpotentially young. Aquifer areas were considered to have a low susceptibility if less than 25 percent of the samples were classified as oxic-potentially young.

The three primary well types sampled by NAWQA (shallow monitoring wells near the water table, domestic wells, and public-supply wells) generally represent different depth zones and (or) areas of the principal aquifers. For the parts of aquifers near the water table in agricultural areas, the aquifers most susceptible to changes in nitrate concentrations were the Columbia Plateau basin-fill aquifers, Eastern glacial aquifers, and the West-central glacial aquifers. None of the aquifers had a low susceptibility to changes in

nitrate concentrations. For the parts of aquifers that provide domestic water supplies, the aquifers most susceptible to changes in nitrate concentrations were the Northern Atlantic Coastal Plain aquifer system and the Early Mesozoic Basin, Valley and Ridge carbonate-rock, and Piedmont and Blue Ridge crystalline-rock aquifers in the eastern United States; the Ozark Plateaus aquifer system in parts of Missouri and Arkansas; and the Central Valley, Columbia Plateau basalticrock, and Snake River Plain basaltic-rock aquifer systems in the West. The least susceptible aquifers were the Texas Coastal Uplands and Denver Basin aquifer systems. For the parts of aquifers that provide public water supplies, the aquifers most susceptible to changes in nitrate concentrations were the Eastern glacial aquifers and the California Coastal Basin, Basin and Range basin-fill, and High Plains aquifers in the West. The least susceptible aquifer was the Cambrian-Ordovician aquifer system in the upper Midwest.

Principal-aquifer lithology groups with the largest percentage of domestic-well networks considered to have a high susceptibility to changes in nitrate concentrations were the basaltic- and other volcanic-rock aquifer systems, carbonate-rock aquifers, and crystalline-rock aquifers. The lithology groups with the smallest percentage of networks considered to have a high susceptibility to changes in nitrate concentrations were the glacial aquifers and sandstone aquifers. There are important geologic differences between the aquifer lithology groups with high and low susceptibilities to changes in nitrate concentrations. The relatively large percentage of high-susceptibililty networks in the basaltic- and other volcanic-rock aquifer systems, carbonate-rock aquifers, and crystalline-rock aquifers may indicate the importance of fractures and karst features in promoting the rapid movement of oxic-potentially young groundwater in those aquifers. The relatively small percentage of high-susceptibility networks in the glacial and sandstone aquifers reflects geologic characteristics of those aquifers that support anoxic redox conditions (high electron-donor content) and inhibit water movement (fine-grained confining layers).

For networks of monitoring and domestic wells that were approximately collocated, the monitoring-well networks had the higher percentage of samples classified as oxic-potentially young, indicating that susceptibility tended to be higher at the shallower depths of the monitoring wells. For networks of domestic and public-supply wells that were approximately collocated, the public-supply wells had the higher percentage of samples classified as oxic-potentially young, indicating that susceptibility tended to be higher in the vicinity of publicsupply wells than in the vicinity of domestic wells even though the public-supply wells had larger median well depths. Previous studies found that high rates of pumping in publicsupply wells with long screens induced more rapid downward movement of young groundwater than did domestic wells, which had shorter screens and were less heavily pumped. The data from this study are generally consistent with those findings.

Introduction

Is groundwater quality getting better or worse, why, and what will happen in the future? These are some of the important questions being addressed by the National Water-Quality Assessment (NAWQA) Program of the U.S. Geological Survey (USGS). The NAWQA Program is using multiple approaches to measure and explain trends in concentrations of nitrate in principal aquifers of the United States. Near decadal sampling of selected NAWQA well networks has provided a preliminary determination of where changes in concentrations of chloride, dissolved solids, and nitrate in groundwater have occurred (Rupert, 2008; Lindsey and Rupert, 2012). Because those studies do not include all the NAWQA well networks, a determination has yet to be made as to what might be expected in networks from which time-series data have not been collected. Characterizing aguifer susceptibility to changes in nitrate concentrations on the basis of data collected from all the NAWQA well networks would be a step toward extrapolating findings from those studies to broader regions.

Long-term changes in concentrations of nitrate in groundwater are controlled by factors such as nitrogen input history at the land surface, denitrification in the aquifer, and location in the flow system (Clark and others, 2008; Burow and others, 2008a,b; Kauffman and others, 2001; McMahon and others, 2008a,b). Nitrate concentrations in groundwater increased over several decades in many agricultural areas of the United States following the dramatic increase in fertilizer usage that began in the late 1940s (see summary by Puckett and others, 2011). Denitrification is the microbial reduction of nitrate to nitrogen gas (N_2) and in some aquifers it is an important process for decreasing nitrate concentrations (Böhlke and others, 2002; Green and others, 2008; Tesoriero and Puckett, 2011). Aquifers containing oxic shallow groundwater are more susceptible to changes in nitrate concentrations than aquifers containing anoxic deep groundwater (Dubrovsky and others, 2010). This pattern occurs because nitrate persists in oxic groundwater and is removed by denitrification in

anoxic groundwater, and deep groundwater generally is older, sometimes predating nitrogen inputs by humans at the land surface, and contains a broader mix of water of differing ages and sources than shallow groundwater. Thus, redox-age classifications could provide a framework for characterizing the susceptibility of aquifers to changes in nitrate concentrations and such a framework could be used for interpreting timeseries monitoring data.

To a certain extent, this type of redox-age assessment has already been done using statistically based models of groundwater vulnerability (Rupert, 1998; Nolan and Hitt, 2006; Gurdak and Qi, 2006; Rupert and Plummer, 2009). Vulnerability models sometimes incorporate redox and groundwaterage information, but use surrogate variables, such as soil type and well depth (Nolan and Hitt, 2006). More direct measures of redox conditions and groundwater age are available, such as concentrations of dissolved oxygen, chlorofluorocarbons, and sulfur-hexafluoride, and detections of tritium, pesticide compounds, or volatile organic compounds (VOCs).

The purpose of this report is to characterize the susceptibility of selected principal aquifers of the United States to changes in nitrate concentrations on a basis of the redox-age classification scheme developed in this report. Redox classes are defined by concentrations of dissolved oxygen. Groundwater-age classes are defined by concentrations of tritium, nitrate, pesticide compounds, VOCs, chlorofluorocarbons, sulfur hexafluoride, and (or) helium. The redox-age classification scheme uses NAWQA water-quality data collected from 39 principal aquifers and 5 alluvial aquifers from 1991 to 2010.

Methods

This section describes the well networks and waterquality data used in the study, and the principal aquifers in which the networks are located. In addition, the redox and groundwater-age classes used to characterize the aquifers are defined.

Well Selection

Wells included in this study were used in NAWQA studies designed to describe the quality of water withdrawn from principal aquifers and used for drinking (termed major-aquifer studies or MASs, and source-water studies or DWGSs), and studies of shallow groundwater within specific land-use settings (termed land-use studies or LUSs). MASs focused on the quality of groundwater resources without being linked to a specific land use and used data mostly from existing domestic wells. DWGSs focused on the quality of groundwater from public-supply wells. Water samples from MAS and DWGS wells were collected before any treatment or pressure tanks and therefore do not represent water consumed for drinking. LUSs targeted the uppermost recently recharged groundwater to identify the effects of the overlying land use and used data mostly from monitoring wells and some production wells. Generally, MAS networks covered larger geographic areas and their wells were deeper than LUSs. Gilliom and others (1995) presented a general discussion of NAWQA well networks. Individual MASs, DWGSs, and LUSs are described in reports for individual NAWQA study areas (U.S. Geological Survey, 2011). Data for a total of 6,593 wells from networks in 39 principal aquifers and 5 alluvial aquifers were used in this study. Locations of the principal aquifers are shown in fig. 1.

Sources of Data

Many of the NAWQA wells have been sampled more than once, but the water-quality data used in this study primarily represent the most recently collected water sample from each well. Water samples included in this study were collected from 1991 to 2010. Methods for collecting and analyzing groundwater samples for the NAWQA program are well documented (U.S. Geological Survey, 2011) and are not repeated here. Water-quality and groundwater-age data of primary interest in this study are concentrations of dissolved oxygen, nitrate, pesticide compounds, volatile organic compounds (VOCs), chlorofluorocarbons, sulfur hexafluoride, tritium, and helium. Dissolved oxygen was measured in the field at the time of sample collection. Nitrate, pesticide compounds, and VOCs were analyzed at the USGS National Water Quality Laboratory in Denver, Colorado. Chlorofluorocarbons and sulfur hexafluoride were analyzed at the USGS Chlorofluorocarbon Laboratory in Reston, Virginia. Tritium was measured at the USGS Tritium Laboratory in Menlo Park, California, the USGS Noble Gas Laboratory in Denver, Colorado, or the Noble Gas Laboratory of the Lamont-Doherty Earth Observatory in Palisades, New York. Helium was measured at the USGS Noble Gas Laboratory in Denver, Colorado, or the Noble Gas Laboratory of the Lamont-Doherty Earth Observatory in Palisades, New York. The data can be found in the USGS National Water Information System (NWIS) or in Hinkle and others (2010).

Aquifer Groups and Geology

This study primarily examined 39 principal aquifers (fig. 1). Principal aquifers are defined as aquifers that are regionally extensive and can yield useable quantities of water (U.S. Geological Survey, 2003). The aquifers are broadly grouped into eight lithologic groups: basaltic and other volcanic rocks, carbonate rocks, crystalline rocks, glacial sand and gravel, sandstone and carbonate rocks, sandstone, semiconsolidated sand, and unconsolidated sand and gravel (U.S. Geological Survey, 2003). Five relatively small alluvial aquifers also were examined and they are considered to be part of the unconsolidated sand and gravel lithology group.

Redox Classification

Redox conditions in many of the principal aquifers were described on a regional basis (McMahon and others, 2009) using the redox framework developed by McMahon and Chapelle (2008). That framework uses a dissolvedoxygen concentration of 0.5 milligram per liter (mg/L) as the threshold between oxic and anoxic conditions. The framework has additional redox subclasses for anoxic conditions, but for the purposes of this report only two redox classes are considered-oxic (dissolved oxygen concentration greater than or equal to 0.5 mg/L) and anoxic (dissolved oxygen concentration less than 0.5 mg/L). Consideration of just two redox classes is appropriate for this report because oxygen reduction typically is the first redox process to occur in groundwater and denitrification typically is the first anoxic redox process to follow oxygen reduction when nitrate is present in groundwater (Chapelle and others, 1995; McMahon and Chapelle, 2008). The susceptibility of aquifers to changes in nitrate concentrations would be greater in oxic groundwater than in anoxic groundwater (Rupert, 2008), although the susceptibility also could be high in anoxic groundwater that is actively undergoing denitrification.

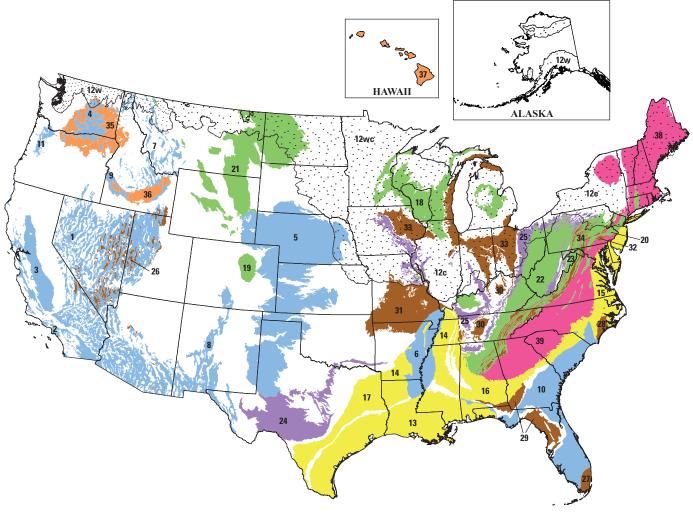

The use of a dissolved-oxygen concentration of 0.5 mg/L as the threshold for onset of denitrification probably is conservative. As discussed by Green and others (2010), mixing in heterogeneous aquifers and in well screens can result in the co-occurrence of geochemical indicators of denitrification with dissolved oxygen concentrations greater than 0.5 mg/L. Several field studies have reported apparent threshold concentrations for the onset of denitrification in the range of about 1 to 2 mg/L (Böhlke and others, 2002; McMahon and others, 2004; Böhlke and others, 2007; Green and others, 2008; Tesoriero and Puckett, 2011).

Groundwater-Age Classification

The substantial increase in fertilizer usage in the United States beginning in about the late 1940s is an important event in the context of this study because fertilizer represents the largest single anthropogenic source of nitrogen in the country (Dubrovsky and others, 2010), and an increase in usage of fertilizer has been linked to increased concentrations of nitrate in groundwater (see review by Puckett and others, 2011). Given this history, a useful tracer of groundwater age for this study would differentiate between water recharged before and after the early 1950s. For the purposes of this report these waters are referred to as old and young groundwater, respectively. The susceptibility of aquifers to changes in nitrate concentrations would be greater in young groundwater than in old groundwater.

Tritium was used to differentiate between old and young groundwater in this study. Tritium is a radioactive isotope of hydrogen with a half-life of 12.32 years (Lucas

and Unterweger, 2000). Small concentrations of tritium are produced naturally by interactions between the atmosphere and cosmic rays. It is an excellent tracer of water movement because it is part of the water molecule. In general, tritium in groundwater originates from precipitation. Because tritium is radioactive, its concentration in groundwater decreases over time as a result of radioactive decay. Before the onset of atmospheric testing of nuclear weapons in about 1953 (prebomb), the tritium content of precipitation in the conterminous United States probably ranged from about 2 to 8 tritium units (TU) (Kaufman and Libby, 1954; Thatcher, 1962). As a result of radioactive decay, groundwater derived from precipitation that fell before 1953 would have contained less than 0.5 TU tritium in 2010 (the most recent samples used in this study), but it could have contained upwards of about 1 TU in 1991 (the earliest samples used in this study). The tritium content of precipitation increased substantially after the onset of atmospheric nuclear weapons testing but has slowly decreased from its peak in the early 1960s. Even with the variability in tritium content of precipitation over time, most groundwater in the United States exclusively derived from precipitation that fell since 1953 (postbomb) contained more than 0.5 TU in 2010. On the basis of this information, water samples with tritium concentrations less than 0.5 TU were considered to be potentially old groundwater (recharged before the early 1950s), and water samples with tritium concentrations greater than or equal to 0.5 TU were considered to be potentially young groundwater (recharged after the early 1950s). For comparison, several other studies have used tritium concentrations ranging from about 0.2 to 1 TU as the cutoff between old and young groundwater (Michel and Schroeder, 1994; Plummer and others, 2004; Manning and others, 2005; Landon and others, 2010a).

Because only 39 percent of the samples that were assigned to a groundwater-age class had tritium data, other indicators of groundwater age were used for the samples that did not have tritium data. These indicators include detections of pesticide compounds and (or) VOCs; elevated concentrations of nitrate; and (or) dating with chloroflurocarbons, sulfur hexafluoride, or tritium/helium-3 (Plummer and others, 1993; Kolpin and others, 1995; Busenberg and Plummer, 2000; Shelton and others, 2001; Manning and others, 2005; Plummer and others, 2008). The water-quality data set used in this study contained information for as many as 155 pesticide compounds and 85 VOCs. Minimum detection levels for the pesticide compounds ranged from 0.000057 to 0.021 microgram per liter (µg/L). For the VOCs, minimum detection levels ranged from 0.001 to 0.3 µg/L. Samples that did not have tritium data but had a detection of a pesticide compound or a VOC were considered to be potentially young groundwater. Samples that did not have tritium data but had a nitrate concentration greater than 1.3 milligrams of nitrogen per

liter (mg-N/L) also were considered to be potentially young groundwater. This concentration represents the 75th percentile concentration of nitrate in groundwater samples with tritium concentrations less than 0.5 TU. For comparison, Nolan and Hitt (2003) proposed a national background nitrate concentration of about 1 mg-N/L and Mueller and Helsel (1996) proposed a background concentration of 2 mg-N/L. Background nitrate concentrations in groundwater are likely to vary regionally and locally, but that variability was not taken into account in this study. Some samples were dated using chloroflurocarbons, sulfur hexafluoride, or tritium/helium-3 (Hinkle and others, 2010), and those data were used to determine the presence of young groundwater in samples for which tritium data were unavailable. For samples that had no tritium, chlorofluorocarbon, sulfur-hexafluoride, and tritium/helium-3 data, or detections of a pesticide compound or VOC, and had a nitrate concentration of less than or equal to 1.3 mg-N/L, the age was considered to be potentially old. The criteria used to assign redox-age classes to groundwater samples are summarized in table 1.

The approach for classifying groundwater ages does not consider mixing, which is why the age determinations are qualified as being potentially old or young. It is likely that some groundwater classified as being potentially old contained a component of young groundwater, and vice versa (Weissmann and others, 2002; Manning and others, 2005; Plummer and others, 2008). For example, 54 percent of the samples that were classified as potentially old on the basis of tritium concentrations less than 0.5 TU would have been classified as potentially young using just the pesticide compound, VOC, and nitrate data. Twenty-one percent of the samples that were classified as being potentially young on the basis of tritium concentrations greater than or equal to 0.5 TU would have been classified as potentially old using just the pesticide compound, VOC, and nitrate data. Thus, some samples overlapped the age classes used in this report. Another potential limitation is that some VOCs could be present in groundwater recharged before 1950 either from natural sources or solvent and fuel use in the early 20th century. Chloroform, the most commonly detected VOC in the Nation's groundwater (Zogorski and others, 2006), has both natural and man-made sources (McCulloch, 2003). Although the presence of tritium, pesticide compounds, VOCs, or elevated concentrations of nitrate in a sample generally indicates that the sample contained a fraction of young groundwater (Plummer and others, 2008), it does not indicate how much. Techniques are available for estimating the fractions of old and young groundwater in samples (Plummer and others, 2003; Manning and others, 2005), but the data required for that analysis were not available for most of the samples used in this study. Ideally, one would analyze all the water samples for a comparable set of tracers that characterize groundwater

6 Use of Classes to Characterize Susceptibility of Principal Aquifers to Changes in Nitrate Concentrations, 1991 to 2010

Table 1. Criteria used to assign redox-age classes to groundwater samples. Young groundwater is defined as water recharged since the early 1950s, and old groundwater is defined as water recharged before the early 1950s. Age classes are labeled as potentially young or old because some samples probably represent a mixture of ages and the fractions of young and old water in them are unknown.

 $[\geq$, greater than or equal to; >, greater than; \leq , less than or equal to; < less than; mg/L, milligrams per liter; mg-N/L, milligrams of nitrogen per liter; TU, tritium units]

Class	Criteria
	Redox class
Oxic	Dissolved oxygen $\geq 0.5 \text{ mg/L}$
Anoxic	Dissolved oxygen <0.5 mg/L
	Age class
Potentially young	(a) If tritium data are available
	Tritium concentration ≥0.5 TU
	(b) If no tritium data are available
	Detection of at least one pesticide compound or
	Detection of at least one volatile organic compound or
	Nitrate concentration >1.3 mg-N/L or
	Dated using chlorofluorocarbons, sulfur hexafluoride, or tritium/helium-3
Potentially old	(c) If tritium data are available
	Tritium concentration <0.5 TU
	(d) If no tritium, chlorofluorocarbon, sulfur hexafluoride, or tritium/helium-3 data are available
	No detection of pesticide compounds and
	No detection of volatile organic compounds and
	Nitrate concentration ≤ 1.3 mg-N/L

age at multiple time scales to distinguish between water that is completely old or young, or is mixed (Landon and others, 2010a). Despite the limitations of the approach used in this report to classify groundwater age, the approach still provides useful information at the regional scale examined in this report, as is described in the next section.

Evaluation of Redox-Age Classes

Two approaches were used to evaluate whether the redoxage classes described in table 1 could provide useful information on the susceptibility of principal aquifers to changes in nitrate concentrations. In the first approach, redox-age classes assigned to water samples from as many as 6,489 wells were evaluated in relation to well depth, well type, and aquifer confinement to see if the redox-age classes made sense hydrologically. In the second approach, redox-age classes assigned to water samples from 1,111 trend wells that were sampled at near decadal time scales (Lindsey and Rupert, 2012) were evaluated in relation to changes in nitrate concentrations in those samples to determine which redox-age classes had the largest and smallest changes in nitrate concentrations.

Oxic-potentially young water was mostly associated with relatively shallow monitoring and domestic wells completed in unconfined aquifers, whereas anoxic-potentially old water was mostly associated with deeper domestic wells completed in unconfined and confined aquifers (table 2). In general, the median well depths associated with each of the four primary redox-age classes increased in the order of anoxic-potentially young, oxic-potentially young, oxic-potentially old, and anoxic-potentially old (table 2). The fact that potentially young water came from shallower wells than potentially old water makes sense hydrologically and is consistent with what is known about groundwater-age stratigraphy in the principal aquifers (McMahon and others, 2011; Puckett and others, 2011).

Within a given redox class, the difference in median well depths between age criteria (a) and (b) was smaller than the difference between criteria (c) and (d) (tables 1 and 2). This could mean that age criteria (a) and (b), used to classify potentially young water, are more comparable than age criteria (c) and (d), used to classify potentially old water. For potentially old water, the median well depth was 1.6 to 2.0 times greater for samples classified using criterion (c) than it was for samples classified using criterion (d). This could indicate that small nitrate concentrations and the absence of detections of pesticide compounds and VOCs (criterion (d)) is not always indicative of old water. In some instances, the smaller median well depth for samples classified using criterion (d) might indicate young groundwater that was not impacted by anthropogenic chemicals, in which case criterion (d) would overestimate the amount of potentially old water in an aquifer. For the purpose of characterizing the susceptibility of an aquifer to changes in nitrate concentrations, overestimation of the amount of potentially old water is probably less of an issue in anoxic water than oxic water because of the higher denitrification potential in

	Well depth below land surface	below face		We	Well type		Aquif	Aquifer confinement	nt
Redox-age class	Number of samples	Median (m)	Number of samples	Shallow monitoring wells (%)	Domestic wells (%)	Public- supply wells (%)	Number of samples	Confined (%)	l Unconfined (%)
Oxic-potentially young, criterion (a)	1,489	31	1,393	46	43	10	1,106	18.1	81.9
Oxic-potentially young, criterion (b)	2,540	22	2,380	46	41	13	1,720	12.5	87.5
Oxic-potentially old, criterion (c)	321	70	301	16	99	18	254	20.5	79.5
Oxic-potentially old, criterion (d)	319	43	305	25	55	20	181	21.5	78.5

Table 2. Redox-age classes for water samples collected from principal aquifers in the United States and median well depth, well type, and aquifer confinement.

8 Use of Classes to Characterize Susceptibility of Principal Aquifers to Changes in Nitrate Concentrations, 1991 to 2010

anoxic water. For each redox class, the median well depth for potentially old water classified using criterion (d) still was larger than the median well depth for potentially young water, regardless of whether age criterion (a) or (b) was used to classify that water. Overall, age criterion (d) probably is indicative of old water in some instances and young water in others; of the eight possible redox-age classes (tables 1 and 2), the oxic-potentially old classification based on age criterion (d) probably has the greatest uncertainty with respect to characterizing aquifer susceptibility to changes in nitrate concentrations. The oxic-potentially old, criterion (d), redoxage class was assigned to 5 percent of the 6,593 samples used in this study.

Overall, samples classified as oxic-potentially young showed the largest changes in nitrate concentrations for pairs of samples collected at near decadal time scales, whereas samples classified as anoxic-potentially old showed the smallest changes (fig. 2). This result is consistent with what would be predicted on the basis of the discussions in the "Redox Classification" and "Groundwater-Age Classification" sections of this report. Changes in nitrate concentrations for the samples classified as oxic-potentially old and anoxicpotentially young were intermediate in scale. Despite the relatively large uncertainty in age that could be associated with the oxic-potentially old classification based on age criterion (d), it actually had a smaller interquartile range for changes in nitrate concentrations than the same redox-age class based on age criterion (c) (fig. 2). Although nitrate concentration was one of the criteria used to assign groundwater-age classes (table 1), it is unlikely that using nitrate-concentration data in this manner biased the comparison between redox-age classes and changes in nitrate concentrations in paired samples (fig. 2). Age classes were assigned to just one of the paired samples (typically the more recently collected sample), and then compared to *changes* in nitrate concentrations. A high nitrate concentration in a single groundwater sample may be an indicator of recently impacted groundwater, and that is the point of using it as an age indicator, but it is not a guarantee that changes in nitrate concentrations occurred at the time scale of the trends sampling.

In general, only the more recently collected sample was assigned a redox-age class for pairs of samples collected at near decadal time scales. An attempt was made to assign redox-age classes to both pairs of samples, but it quickly became apparent that the age assignments would not be comparable in most cases. This is because the paired samples usually were not analyzed for the same suite of pesticide compounds and VOCs, and often only one of the samples was analyzed for tritium.

Because data for dissolved oxygen typically were available for both pairs of samples, changes in nitrate concentrations were compared to changes in redox classification. The largest changes in nitrate concentrations occurred in pairs of samples that were both classified as oxic (fig. 3). This indicates that most of the changes in

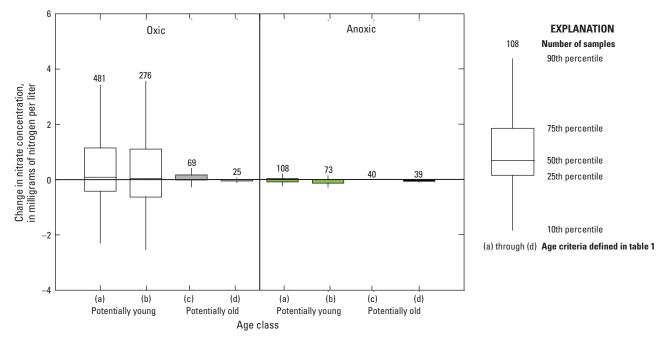

Figure 2. Change in nitrate concentration for pairs of samples collected from selected wells in the United States at near decadal time scales in relation to the redox-age class of the more recently collected sample.

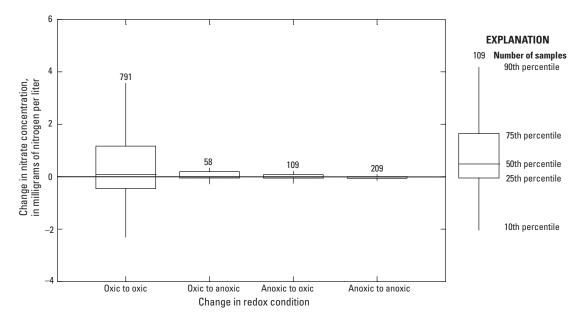

Figure 3. Change in nitrate concentration for pairs of samples collected from selected wells in the United States at near decadal time scales in relation to the change in redox condition.

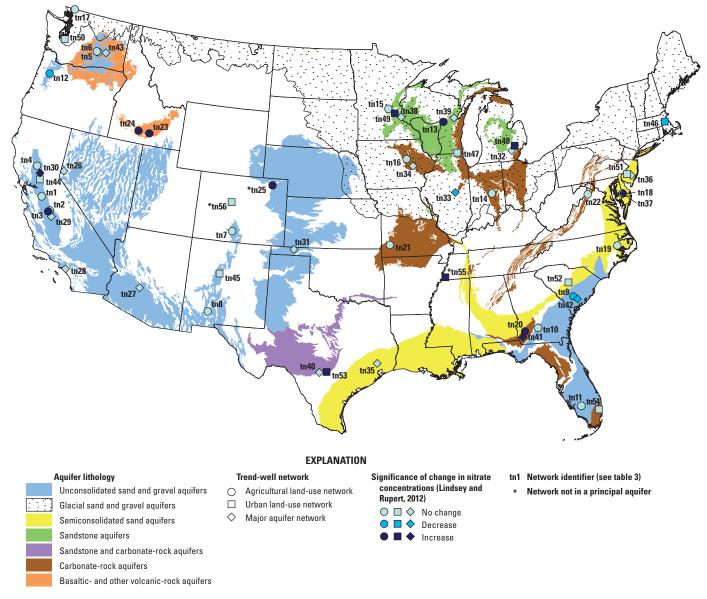

nitrate concentrations were not a result of changes in redox conditions in the aquifer but were more likely a result of changing nitrogen inputs at the land surface and (or) changing fractions of young and old water in the sample pairs.

On the basis of the evaluation presented above, the redox-age classes in table 1 can provide useful information on aquifer susceptibility to changes in nitrate concentrations. For the remainder of this report, results for age criteria (a) and (b) were combined by redox class and the same was done for age criteria (c) and (d). This results in four redox-age classes (oxic-potentially young, oxic-potentially old, anoxicpotentially young, and anoxic-potentially old) instead of eight.

Relation Between Redox-Age Classes and Changes in Nitrate Concentrations in Trend-Well Networks

The data in figure 2 indicate a strong relation between redox-age class and the change in nitrate concentration in pairs of samples collected from individual wells at near decadal time scales. The relation between redox-age classes and changes in nitrate concentrations also was examined at the well-network level because the well networks, unlike single wells, were designed to be statistically representative of large aquifer areas. Lindsey and Rupert (2012) analyzed nitrate concentrations in water samples collected at near decadal time scales from 56 NAWQA well networks (fig. 4) and found statistically significant changes in concentrations at greater than a 90-percent confidence level in 18 (32 percent) of them. Lindsey and Rupert (2012) did not analyze nitrogen input histories in those 18 networks, but presumably the significant changes in nitrate concentrations were related to changes in nitrogen inputs at the land surface in some of them. Other factors such as variations in recharge rates, depth to groundwater, or pumping also could have affected nitrate concentrations (Rosen and others, 2008). Redox-age classes assigned to water samples from the LUS and MAS networks analyzed by Lindsey and Rupert (2012) are shown in table 3.

Results from 6 of 25 agricultural LUS networks for which near decadal changes could be evaluated showed significant increases in nitrate concentrations and 2 networks showed significant decreases (Lindsey and Rupert, 2012) (fig. 5 and table 3). Agricultural networks that showed significant increases in concentrations were located in the Central Valley aquifer system, Central glacial aquifers, Floridan aquifer system, Snake River Plain basaltic-rock aguifer system, and the South Platte River alluvial aquifer (fig. 4 and table 3). At least 75 percent of the samples in 7 of the 8 networks that showed significant changes in nitrate concentrations were classified as oxicpotentially young (fig. 5), and no more than 4 percent of the samples were classified as anoxic-potentially old (table 3). Samples from urban LUSs generally showed similar results, with 4 of 13 networks showing significant increases in nitrate concentrations and 1 showing a significant decrease. At least

75 percent of the samples in 4 of the 5 networks that showed significant changes in nitrate concentrations were classified as oxic-potentially young (fig. 5), and no more than 5 percent of the samples were classified as anoxic-potentially old (table 3). For 11 of the 17 agricultural LUSs and 7 of the 8 urban LUSs that showed no significant changes in nitrate concentrations, at least 75 percent of their samples also were classified as oxic-potentially young (table 3). Only about 11 percent of the LUS networks studied by Lindsey and Rupert (2012) had more than 10 percent of their samples classified as potentially old (table 3), which is not surprising given that NAWQA land-use studies typically targeted the most recently recharged groundwater.

Three of 18 MASs showed significant increases in nitrate concentrations, and two showed significant decreases (Lindsey and Rupert, 2012) (fig. 4 and table 3). Networks that showed

significant increases in nitrate concentrations were located in the Central Valley, Northern Atlantic Coastal Plain, and Floridan aquifer systems. Only one of the MASs (acfbsus1) that showed a significant change in nitrate concentrations had more than 75 percent of the samples classified as oxicpotentially young. For the other four networks, 0 to 54 percent of the samples were classified as oxic-potentially young (fig. 5 and table 3). On closer inspection, the LUS and MAS results are not necessarily inconsistent because most of the wells with large changes in nitrate concentrations in these MAS networks with significant changes were oxic-potentially young. For the two MAS networks (lirbsus1 and santsus2) that showed significant decreases in nitrate concentrations, 62 to 100 percent of the samples were classified as anoxic and 69 to 79 percent of the samples were classified as potentially old (table 3). The network-level changes in nitrate concentrations for lirbsus1 and santsus2 were -0.04 and -0.05 mg-N/L, respectively (fig. 5 and table 3), and the change in concentration for almost all the sample pairs was less than 0.1 mg-N/L (figs. 6A, B). More than 50 percent of the data were pairs of nondetects (Lindsey and Rupert, 2012). The one sample in those two networks than did show a relatively large change in concentration (greater than 1 mg-N/L) was classified as oxic-potentially young (fig. 6B). The predominance of small changes in nitrate concentrations in these two networks would be expected for aquifers that contained large percentages of anoxic and (or) potentially old water. The two networks (sacrsus1 and dlmvsus1) that showed significant increases in nitrate concentrations, but for which the percentage of samples classified as oxic-potentially young was less than 75 percent (48 to 54 percent), had larger absolute changes in nitrate concentrations (0.14 mg-N/L) than lirbsus1 and santsus2 (fig. 5). The concentration changes for sacrsus1 and dlmvsus1, however, were smaller than the change for the MAS network acfbsus1 (0.32 mg-N/L) that had more than 75 percent of its samples classified as oxic-potentially young (fig. 5 and table 3). Closer inspection of the data from sacrsus1 and dlmvsus1 shows that most of the large changes in concentrations occurred in samples that were classified as oxic-potentially young (figs. 6C, D). Three samples from the dlmvsus1 study that were classified as anoxic-potentially young showed concentration changes of 4.9 to 7.5 mg-N/L (fig. 6D); redox conditions in these samples apparently were anoxic but did not result in complete

Two of the 13 MASs that showed no significant changes in nitrate concentrations had at least 75 percent of their samples classified as oxic-potentially young (table 3). The remaining 11 networks had 32 to 71 percent of their samples classified as oxic-potentially young. About 83 percent of the MAS networks studied by Lindsey and Rupert (2012) had more than 10 percent of their samples classified as potentially old, which is a considerably larger percentage than for the agricultural LUS networks. This finding was expected because wells used in the MAS networks typically were deeper than those used in the LUS networks.

denitrification.

The redox-age results for pairs of samples collected from individual wells show that the largest changes in nitrate concentrations primarily occurred in samples that were classified as oxic-potentially young (figs. 2 and 6). A generally similar pattern was observed when samples were aggregated to the level of well networks. For LUS and MAS networks that showed significant changes in nitrate concentrations, the median changes in concentrations were 0.28, 0.14, and -0.05 mg-N/L for networks that had at least 75 percent, at least 25 percent and less than 75 percent, and less than 25 percent of the samples classified as oxic-potentially young, respectively. On the basis of the data shown in figures 2 and 5, aquifer areas (as defined by well networks) in which at least 75 percent of the samples were classified as oxic-potentially young were considered to have a high susceptibility to changes in nitrate concentrations (fig. 5). Aquifer areas were considered to have a medium susceptibility to changes in nitrate concentrations if at least 25 percent and less than 75 percent of the samples were classified as oxic-potentially young (fig. 5). Aquifer areas were considered to have a low susceptibility to changes in nitrate concentrations if less than 25 percent of the samples were classified as oxic-potentially young (fig. 5). These definitions of high, medium, and low are used to characterize aquifer susceptibility to changes in nitrate concentrations throughout the remainder of the report. The degree of susceptibility is not intended to indicate that significant changes in concentrations of nitrate will or will not be detected in the future in those areas. Other factors such as nitrogen input history at the land surface, mixing, and lag times related to nitrate transport could cause nitrateconcentration trends to develop over longer time scales than the near decadal time scale examined by Lindsey and Rupert (2012), or not at all.

Redox-Age Classes in Principal Aquifers

The three primary well types sampled by NAWQA generally represent different depth zones and (or) areas of the principal aquifers. Shallow monitoring wells are completed near the water table, whereas domestic and public-supply wells are mostly completed in deeper zones in the aquifers. In this section of the report, redox-age classes assigned to networks of shallow monitoring wells in agricultural areas, domestic wells, and public-supply wells were used to characterize the susceptibility to changes in nitrate concentrations of these different depth zones and (or) areas of the principal aquifers. The susceptibility to changes in nitrate concentrations near the water table in urban areas is not considered here because of the generally small area represented by those networks of shallow monitoring wells, however, redox-age classes and susceptibility rankings for those networks are shown in the Appendix.

Susceptibility to Changes in Nitrate Concentrations Near the Water Table in Agricultural Areas

Redox-age classes were assigned to samples collected from 40 networks of shallow monitoring wells in agricultural areas (fig. 7 and table 4). Most networks (58 percent) had a high susceptibility to changes in nitrate concentrations because at least 75 percent of their samples were classified as oxicpotentially young. Only 10 percent of the networks had a low susceptibility to changes in nitrate concentrations because less than 25 percent of their samples classified as oxic-potentially young (table 4).

¹Network has wells in the Floridan and Southeastern Coastal Plain aquifer systems.

²Network has wells in the Columbia Plateau basaltic-rock and basin-fill aquifer systems.

³Network not in a principal aquifer.

⁴Redox-age classes where determined for the more recently collected samples in each network, and redox-age percentages may not sum to 100 percent because of rounding.

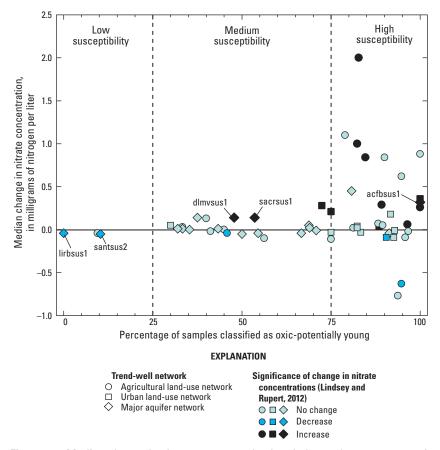

Figure 5. Median change in nitrate concentration in relation to the percentage of samples that were classified as oxic-potentially young in well networks that were sampled at near decadal timescales (concentration data from Lindsey and Rupert, 2012), and the susceptibility of the networks to changes in nitrate concentrations.

For principal aquifers that had at least 2 networks of wells, median percentages of samples classified as oxicpotentially young ranged from about 57 to 96 percent (fig. 8). On the basis of these data, for the parts of aquifers near the water table in agricultural areas, the aquifers most susceptible to changes in nitrate concentrations were the Columbia Plateau basin-fill aquifers, Eastern glacial aquifers, and the West-central glacial aquifers (fig. 8). None of the aquifers had a low susceptibility to changes in nitrate concentrations, which would be indicated by a median percentage of samples classified as oxic-potentially young that was less than 25 percent. The High Plains aquifer had the highest median percentage of samples classified as oxic-potentially old, which generally reflects the low organic-carbon content of sediment and relatively low recharge rates in the aquifer (McMahon and others, 2007). The Central Valley and Surficial aquifer systems had the highest median percentages of samples classified as anoxic-potentially young (fig. 8). Only the Rio Grande aquifer system and the Central glacial aquifers had median percentages of samples classified as anoxic-potentially old that were greater than zero.

Although the median percentages in figure 8 provide a general comparison of redox-age classes between principal aquifers, they do not indicate the substantial redox-age variability that can occur within an aquifer. For the three well networks in the Central Valley aguifer system, the percentage of samples classified as oxic-potentially young ranged from 13 to 90 percent (table 4 and fig. 9), and the percentage of samples classified as anoxic-potentially young ranged from 10 to 83 percent. In the High Plains aquifer, median percentages of samples classified as oxic-potentially old ranged from 10 to 41 percent (fig. 9). In the West-central glacial aquifer, median percentages of samples classified as anoxic-potentially old ranged from 0 to 35 percent (fig. 9). Large intraaquifer redoxage variability was observed in most of the aquifers that had multiple networks of shallow monitoring wells in agricultural areas (table 4).

Distinct patterns in the spatial distribution of networklevel susceptibilities are apparent in some of the aquifers. Networks in the Central glacial aquifers of Indiana and parts of southern Michigan and Wisconsin had medium susceptibilities, whereas networks in glacial aquifers to the

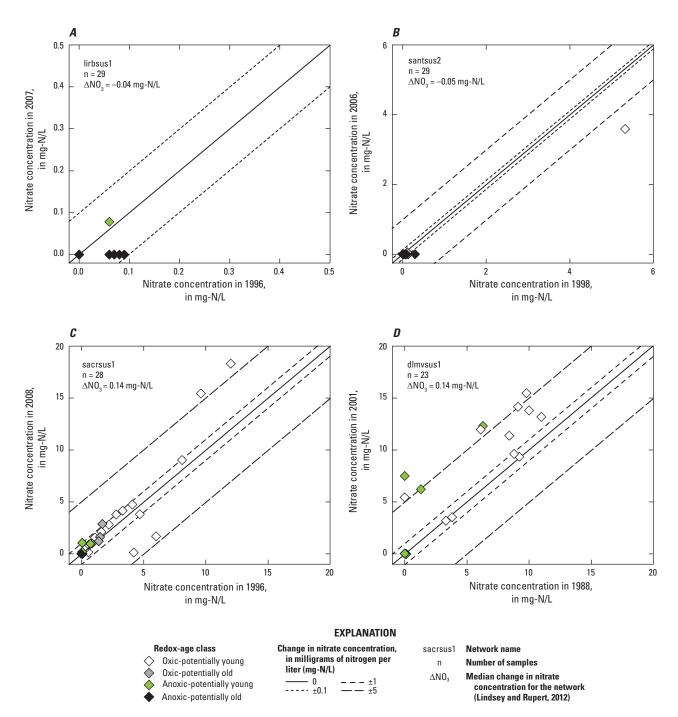

Figure 6. Concentrations of nitrate in pairs of samples collected from selected networks of major-aquifer study wells in the United States at near decadal time scales; (*A*) lirbsus1, (*B*) santsus2, (*C*) sacrsus1, and (*D*) dlmvsus1 networks.

Table 4. Redox-age classes for water samples collected from networks of shallow monitoring wells in agricultural areas in the United States and the susceptibility of the networks to changes in nitrate concentrations (only networks with at least 10 wells are listed).

³Redox-age percentages may not sum to 100 percent because of rounding. ²Network not in a principal aquifer.

18 Use of Classes to Characterize Susceptibility of Principal Aquifers to Changes in Nitrate Concentrations, 1991 to 2010

east and west had high susceptibilities. The areas of medium susceptibility in Indiana had relatively high percentages of samples classified as anoxic-potentially young compared to the surrounding networks with high susceptibilities (fig. 7 and table 4). This difference in redox-age classes between the two areas could indicate shallower depths to water and (or) finer grained sediment in the medium-susceptibility area relative to the high-susceptibility areas, both of which could result in anoxic groundwater. Other studies have reported an increase in concentrations of dissolved organic carbon, probably from the soil zone, and a decrease in concentrations of dissolved oxygen in groundwater with decreasing depths to the water table (Pabich and others, 2001; McMahon and Chapelle, 2008). In the High Plains aquifer, network susceptibility decreased from high in the north to medium in the central and southern parts of the aquifer (fig. 7). This change in

susceptibility corresponds to a north-to-south increase in the percentage of samples classified as oxic-potentially old (fig. 9 and table 4), an increase that is probably related to the north-to-south decrease in recharge and increase in depth to the water table (McMahon and others, 2007). In the Central Valley aquifer system, network susceptibility increased from low in the north to medium and high in the south (fig. 7). The percentage of samples classified as anoxic-potentially young in the northern network was about 2 to 8 times greater than the percentages in the southern networks where oxic-potentially young groundwater predominated (fig. 9 and table 4). The common occurrence of anoxic groundwater in the north may be related to the much shallower depths to the water table in the northern network of wells (median depth 1.1 m) than in the southern networks (median depths 14 to 20 m). Redox-age classes were assigned to samples collected from 105 networks of domestic wells (fig. 10 and table 5). Thirty-one percent of the networks were considered to have a high susceptibility to changes in nitrate concentrations and 17 percent of the networks were considered to have low susceptibilities (table 5). In comparison, 58 percent of the networks of shallow monitoring wells in agricultural areas were considered to have a high susceptibility to changes in nitrate concentrations and 10 percent were considered to have a low susceptibility.

For principal aguifers that had at least 2 networks of domestic wells, the median percentage of samples classified as oxic-potentially young ranged from about 6 to 100 percent (fig. 11), compared to about 57 to 96 percent for the shallow monitoring wells (fig. 8). For the parts of aquifers that provide domestic water supplies, the aquifers most susceptible to changes in nitrate concentrations were the Northern Atlantic Coastal Plain aquifer system and the Early Mesozoic Basin, Valley and Ridge carbonate-rock, and Piedmont and Blue Ridge crystalline-rock aquifers in the eastern United States; the Ozark Plateaus aguifer system in parts of Missouri and Arkansas; and the Central Valley, Columbia Plateau basalticrock, and Snake River Plain basaltic-rock aquifer systems in the West (figs. 10 and 11). For this analysis, western states are considered to be those located west of Minnesota, Iowa, Missouri, Arkansas, and Louisiana. The least susceptible aquifers were the Texas Coastal Uplands and Denver Basin aquifer systems (figs. 10 and 11).

Relatively large intraaquifer variability in redox-age classes was observed in some of the principal aquifers. For the five well networks sampled in the Floridan aquifer system, the percentage of samples classified as oxic-potentially young ranged from 10 to 100 percent (fig. 12). Aquifer confinement probably is an important control on redox-age variability in the Floridan aquifer system. More than 90 percent of the wells in network santsus2 were completed in the confined part of the aquifer and only 10 percent of its samples were classified as oxic-potentially young (table 5). Only 20 percent of the wells in network acfbsus1 were completed in the confined part of the aquifer and 100 percent of its samples were classified as oxicpotentially young. The Central glacial aquifers also showed large redox-age variability (fig. 12), which could be attributed to the diversity of depositional environments represented by well networks in those aquifers. Wells in network uirbsus1 were completed in glacial-moraine sands and gravels and 67 percent of their samples were classified as oxic-potentially young. Wells in network uirbsus2 were completed in glacial-till deposits and 48 percent of their samples were classified as oxic-potentially young. Wells in network lirbsus1 were completed in confined buried-bedrock-valley deposits and 0 percent of their samples were classified as oxic-potentially young. Not all of the aquifers exhibited large variability in redox-age classes. Networks in the Columbia Plateau and Snake River Plain basaltic-rock aguifers had consistently high percentages of samples classified as oxic-potentially young (fig. 12). In contrast, networks in the Texas Coastal Uplands aquifer system had consistently low percentages of samples classified as oxic-potentially young. The number of well networks in each of those aquifers, however, was relatively small compared to the Floridan aquifer system and Central glacial aquifers (fig. 12).

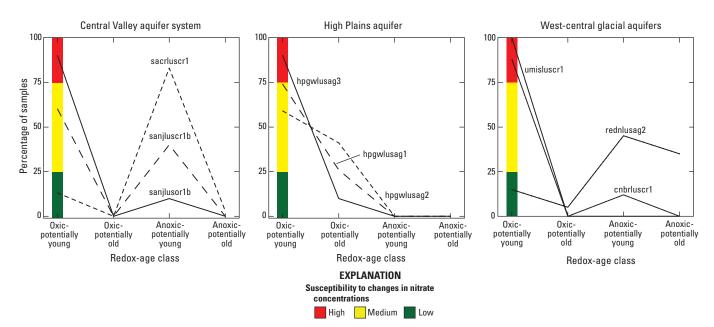

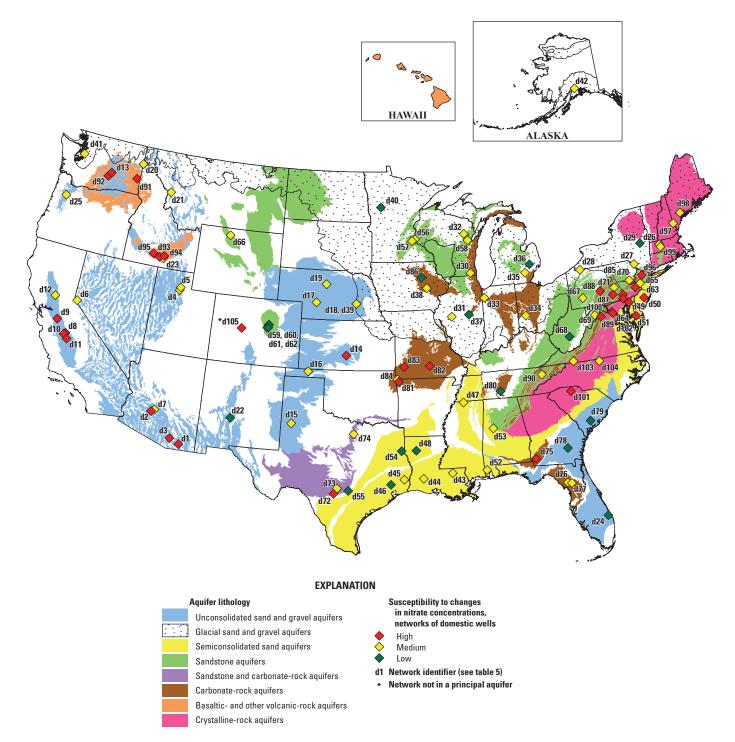

Figure 9. Percentage of samples assigned to the four redox-age classes for networks of shallow monitoring wells in agricultural areas in the Central Valley aquifer system, High Plains aquifer, and the West-central glacial aquifers, and the susceptibility of the networks to changes in nitrate concentrations.

Redox-age classes for water samples collected from networks of domestic wells in the United States and the susceptibility of the networks to changes in nitrate concentrations (only networks with at least 10 wells are listed).—Continued Table 5.

[usg, unconsolidated sand and gravel; gla, glacial sand and gravel; ses, semiconsolidated sand; san, sandstone; ser, sandstone and carbonate rock; car, carbonate rock; bay, basaltic and other volcanic rock; cry, crystalline rock; shading is used to differentiate between aquifer lithologies]

Table 5. Redox-age classes for water samples collected from networks of domestic wells in the United States and the susceptibility of the networks to changes in nitrate concentrations (only networks with at least 10 wells are listed).—Continued

[use, unconsolidated sand and gravel; gla, glacial sand and gravel; scs, semiconsolidated sand; san, sandstone; scr, sandstone and carbonate rock; car, carbonate rock; bay, basaltic and other volcanic rock; cry

Network has wells in the Columbia Plateau basaltic-rock aquifer system and Columbia Plateau basin-fill aquifers. ²Network is part of the High Plains aquifer and West-central glacial aquifers.

³Network has wells in the Mississippi embayment and Texas coastal uplands aquifer systems.

⁴Network not in a principal aquifer.

⁵R edox-age percentages may not sum to 100 percent because of rounding.

24 Use of Classes to Characterize Susceptibility of Principal Aquifers to Changes in Nitrate Concentrations, 1991 to 2010

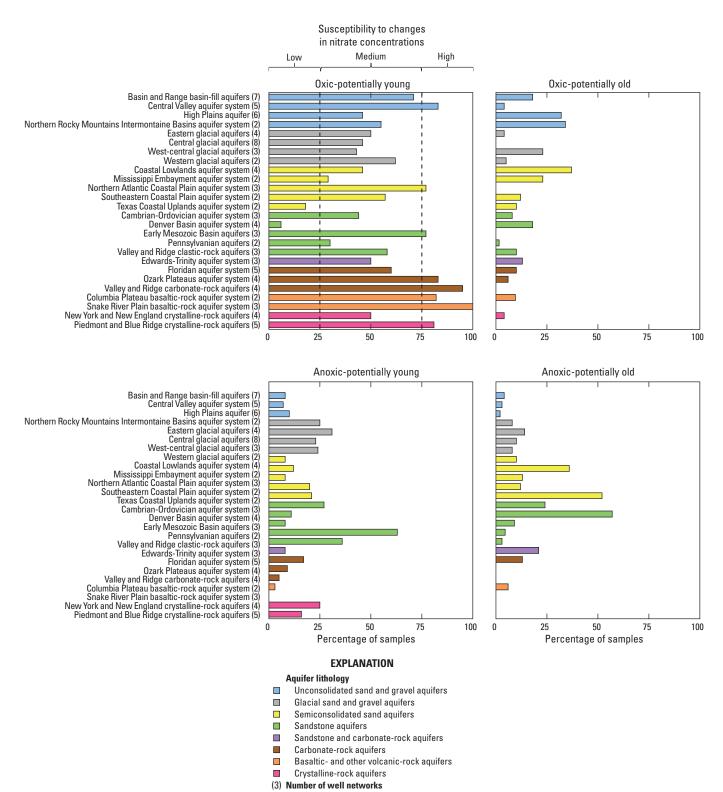

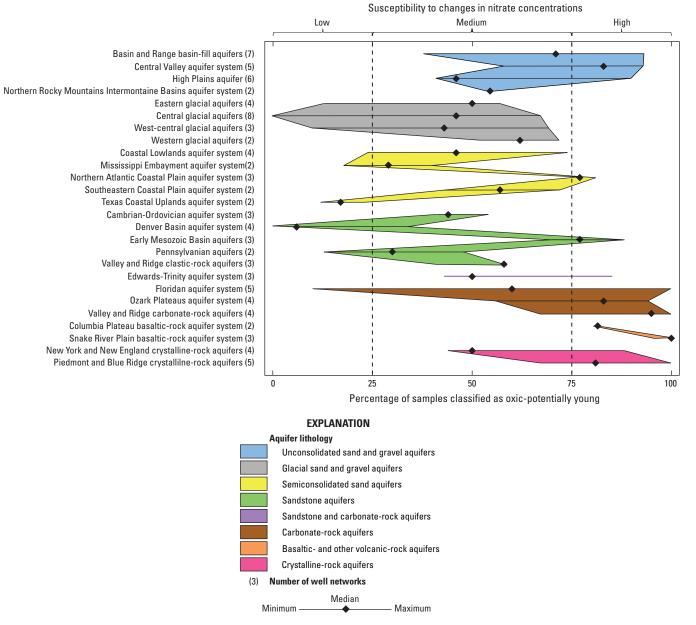

Figure 11. Median percentage of samples assigned to the four redox-age classes for principal aquifers that have at least two

networks of domestic wells, and the susceptibility of the aquifers to changes in nitrate concentrations.

Principal-aquifer lithology groups with the largest percentage of networks considered to have a high susceptibility to changes in nitrate concentrations were the basaltic- and other volcanic-rock aquifer systems (100 percent of networks), carbonate-rock aquifers (50 percent), and crystalline-rock aquifers (44 percent) (table 5 and figs. 10 and 12). These three lithology groups include five of the six domestic-well networks with 100 percent of their samples classified as oxic-potentially young. The lithology groups with the smallest percentage of networks considered to have a high susceptibility to changes in nitrate concentrations were the glacial aquifers (0 percent of networks) and sandstone aquifers (about 13 percent) (table 5 and fig. 10). These two lithology groups include the three well networks with 0 percent of their samples classified as oxic-potentially young (table 5).

There are important geologic differences between the aquifer lithology groups with high and low susceptibilities to changes in nitrate concentrations. The relatively large percentage of high-susceptibilility networks in the basalticand other volcanic-rock aquifer systems, carbonate-rock aquifers, and crystalline-rock aquifers may indicate the importance of fractures and karst features in promoting the rapid movement of oxic-potentially young groundwater in those aquifers (Dubrovsky and others, 2010; McMahon and others, 2011). The relatively small percentage of highsusceptibility networks in the glacial and sandstone aquifers reflects geologic characteristics of those aquifers that support anoxic redox conditions (high electron donor content) and inhibit water movement (fine-grained confining layers).

Domestic-well networks in the eastern and western United States differed with respect to the percentage of samples assigned to certain redox-age classes. The 45 networks located in the western United States had a larger median percentage (13 percent) of samples classified as oxic-potentially old than the 60 networks located in the East (4 percent). Previous studies already noted the presence of oxic groundwater that was sometimes thousands of years old in organic carbon-poor unconsolidated sand and gravel aquifers in the western United States, particularly in the Central Valley and Rio Grande aquifer systems (Plummer and others, 2004; Jurgens and others, 2008), and the Basin and Range basin-fill and High Plains aquifers (Winograd and Robertson, 1982; McMahon and others, 2004). Those aquifers typically have low natural recharge rates and large, thick flow systems. In contrast, networks located in the eastern United States had a larger median percentage (20 percent) of samples classified as anoxic-potentially young than networks located in the West (7 percent). This is not surprising considering the generally shallower depths to water, higher natural recharge rates, and smaller, shallower flow systems in the eastern United States than in the West (Wolock, 2003; Reilly and others, 2008; McMahon and others, 2011). Oxic-potentially old and anoxic-potentially young conditions both reduce aquifer susceptibility to changes in nitrate concentrations, but for different climatic, geologic, and hydrologic reasons.

Fifteen of the domestic-well networks were approximately collocated with networks of shallow monitoring wells in agricultural areas, which provides the opportunity to compare the susceptibility to changes in nitrate concentrations at different depths in the same aquifer area. The median depth of the domestic wells was greater than the median depth of the monitoring wells for each pair of well networks. Overall, the median difference in depth between domestic and monitoring wells was 13 m. For 10 of the 15 pairs of networks, the monitoring-well networks had the higher percentage of samples classified as oxic-potentially young (fig. 13), indicating that susceptibility tended to be higher at the shallower depths of the monitoring wells. For 7 of the 15 pairs of nested networks, susceptibility was in fact higher in the monitoring wells than the domestic wells. Six of those seven pairs are in glacial aquifers (fig. 13). Only 3 of the 15 pairs of nested networks showed higher susceptibilities in the domestic wells than in the monitoring wells. For 5 of the 15 pairs of networks, susceptibilities were generally the same in both well types.

Susceptibility to Changes in Nitrate Concentrations in Parts of Aquifers that Provide Public Water Supplies

Redox-age classes were assigned to samples collected from 39 networks of public-supply wells (fig. 14 and table 6). Thirty-one percent of the networks were considered to have a high susceptibility to changes in nitrate concentrations and 26 percent of the networks were considered to have low susceptibilities (table 6). The percentage of high-susceptibility networks for public-supply wells was the same as for domestic wells, but the public-supply wells had a larger percentage of low-susceptibility networks than the domestic wells.

For principal aquifers that had at least 2 networks of public-supply wells, the median percentage of samples classified as oxic-potentially young ranged from about 7 to 87 percent (fig. 15), compared to about 57 to 96 percent for the shallow monitoring wells (fig. 8) and about 6 to 100 percent for domestic wells (fig. 11). For the parts of aquifers that provide public water supplies, the aquifers most susceptible to changes in nitrate concentrations were the Eastern glacial aquifers and the California Coastal Basin, Basin and Range basin-fill, and High Plains aquifers in the West (figs. 14 and 15). The least susceptible aquifer was the Cambrian-Ordovician aquifer system in the upper Midwest (figs. 14 and 15).

Susceptibility to changes in nitrate concentrations in the networks of public-supply wells appeared to be controlled in part by aquifer confinement and well depth, as was the case for several of the networks of monitoring and domestic wells. Low-susceptibility networks in the Cambrian-Ordovician aquifer system had relatively large well depths (median depths of 124 to 558 m) and large percentages of wells completed in confined parts of the aquifer (median values of 0 to 100 percent) compared to networks in the four aquifers with the highest susceptibilities. Well networks in the Eastern glacial aquifers, for example, had median well depths of 17 to 118 m and percentages of wells completed in confined parts of the aquifer that ranged from 0 to 24 percent.

Well networks sanasus2 and sanasus3, in the California Coastal Basin aquifers (table 6 and fig. 14), had medium susceptibilities even though the median well depths (232 to 294 m) were relatively large and 56 percent of the sanasus2 wells were completed in confined parts of the aquifer. Several factors probably contributed to the susceptibility of those two networks. One factor is long well screens. Median well-screen lengths in the networks accounted for 60 to 68 percent of the well depths. Long well screens could increase the chances of mixing shallow, young water and deep, old water (Landon and others, 2010b). Another possible factor is artificial recharge that occurs in parts of the California Coastal Basin aquifers in southern California that could increase aquifer susceptibility to changes in nitrate concentrations by increasing recharge rates (Hamlin and others, 2002; McMahon and others, 2011). Pumping rate also may affect susceptibility but data were not available to evaluate this factor.

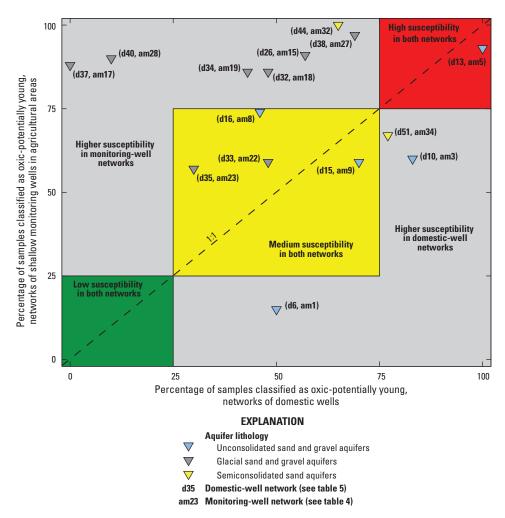

Figure 13. Percentage of samples classified as oxic-potentially young in collocated networks of shallow monitoring wells in agricultural areas and domestic wells, and the susceptibility of the networks to changes in nitrate concentrations.

Only four of the networks of public-supply wells were approximately collocated with networks of domestic wells. The median depth of the public-supply wells was greater than the median depth of the domestic wells for each pair of well networks. Overall, the median difference in depth between public-supply and domestic wells was 39 m, which is three times larger than the median difference in depth between the pairs of domestic- and monitoring-well networks. For three of the four pairs of networks, the public-supply wells had the higher percentage of samples classified as oxic-potentially young (fig. 16), indicating that susceptibility tended to be higher in the vicinity of public-supply wells than in the vicinity of domestic wells even though the public-supply wells had larger median well depths. Although the number of paired networks of public-supply and domestic wells was small, this finding is the opposite of what was observed for shallow monitoring wells and domestic wells (fig. 13). For one pair of public-supply (p24) and domestic-well networks (d45) (fig. 16), the percentage of samples classified as oxic-potentially young was higher for the

domestic wells. This may be due to the fact that only 50 percent of the domestic wells were completed in confined parts of the aquifer (Coastal Lowlands aquifer system) whereas 80 percent of the public supply wells were completed in confined parts of the aquifer. Bruce and Oelsner (2001) studied closely located pairs of domestic and public-supply wells in the High Plains aquifer and found a more frequent occurrence of pesticide compounds and tritium in water from the public-supply wells than in water from the domestic wells. They concluded that high rates of pumping in public-supply wells with long screens induced more rapid downward movement of young groundwater than did domestic wells, which had shorter screens and were less heavily pumped. Jurgens and others (2008) studied a longscreened public-supply well in the Central Valley aquifer system and also found that well construction and operation induced downward movement of young groundwater. The data in figure 16 are consistent with the idea that construction and operation characteristics of public-supply wells can enhance the downward movement of young groundwater (Landon and others, 2010b).

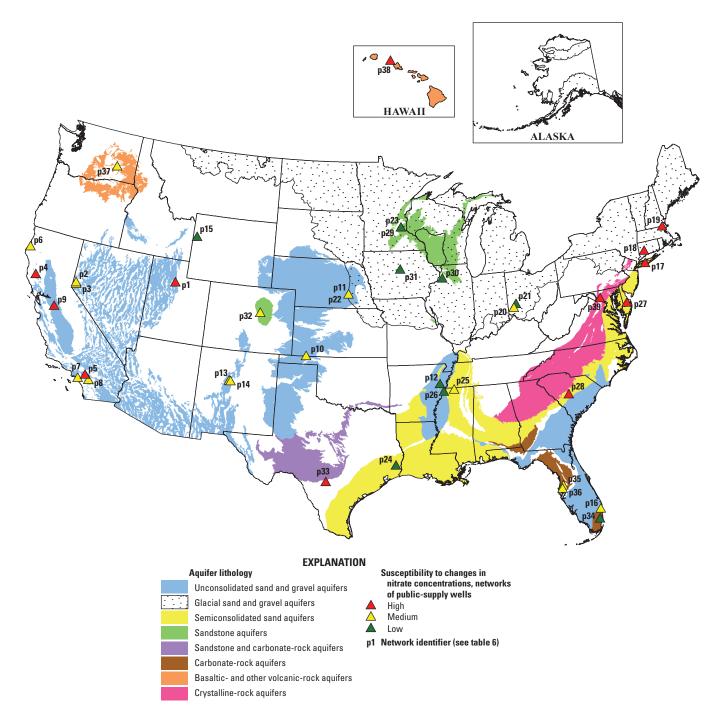

Figure 14. Central locations of networks of public-supply wells and the susceptibility of the networks to changes in nitrate concentrations.

Redox-age classes for water samples collected from networks of public-supply wells in the United States and the susceptibility of the networks to changes in nitrate concentrations (only networks with at least 10 wells are listed). Table 6.

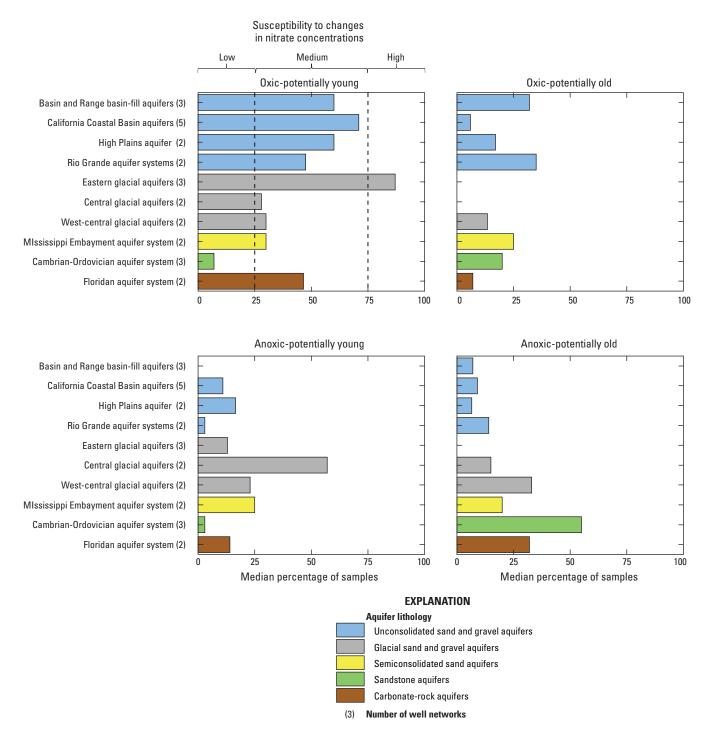

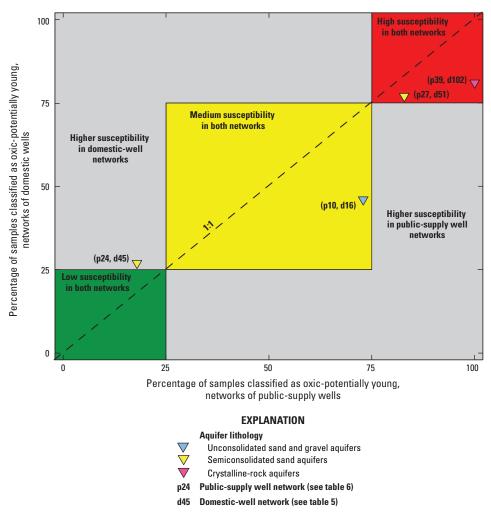

Figure 15. Median percentage of samples assigned to the four redox-age classes for principal aquifers that have at least two networks of public-supply wells, and the susceptibility of the aquifers to changes in nitrate concentrations.

Summary and Conclusions

The National Water-Quality Assessment (NAWQA) Program of the U.S. Geological Survey is using multiple approaches to measure and explain trends in concentrations of nitrate in principal aquifers of the United States. Near decadal sampling of selected well networks is providing information on where long-term changes in nitrate concentrations have occurred. Because those studies do not include all the NAWQA well networks, a determination has yet to be made as to what might be expected in networks from which time-series data have not been collected. Characterizing aquifer susceptibility to changes in nitrate concentrations on the basis of data collected from all the NAWQA well networks would be a step toward extrapolating findings from those studies to broader regions.

The purpose of this report is to characterize the susceptibility of selected principal aquifers of the United States to changes in nitrate concentrations on a basis of the redox-age classification scheme developed in this report. In this study, water samples collected from 6,593 wells in 39 principal aquifers and 5 alluvial aquifers (collected from 1991 to 2010) were assigned to four redox-age classes on the basis of concentrations of dissolved oxygen and various indicators of groundwater age. The redox-age classes are oxicpotentially young, oxic-potentially old, anoxic-potentially young, and anoxic-potentially old. The redox-age assignments were then used to characterize the susceptibility of principal aquifers to changes in nitrate concentrations. Aquifer areas (as defined by well networks) in which at least 75 percent of the samples were classified as oxic-potentially young were considered to have a high susceptibility to changes in nitrate concentrations. Aquifer areas were considered to have a medium susceptibility if at least 25 percent and less than 75 percent of the samples were classified as oxic-potentially young. Aquifer areas were considered to have a low susceptibility if less than 25 percent of the samples were classified as oxic-potentially young.

For the parts of aquifers near the water table in agricultural areas, the aquifers most susceptible to changes in nitrate concentrations were the Columbia Plateau basin-fill aquifers, Eastern glacial aquifers, and the West-central glacial aquifers. None of the aquifers had a low susceptibility to changes in nitrate concentrations. Large intraaquifer redox-age variability was observed in most of the aquifers that had multiple networks of shallow monitoring wells in agricultural areas. For the three well networks in the Central Valley aquifer system, for example, the percentage of samples classified as oxic-potentially young ranged from 13 to 90 percent, and the percentage of samples classified as anoxicpotentially young ranged from 10 to 83 percent.

For the parts of aquifers that provide domestic water supplies, the aquifers most susceptible to changes in nitrate concentrations were the Northern Atlantic Coastal Plain aquifer system and the Early Mesozoic Basin, Valley and Ridge carbonaterock, and Piedmont and Blue Ridge crystalline-rock aquifers in the eastern United States; the Ozark Plateaus aquifer system in parts of Missouri and Arkansas; and the Central Valley, Columbia Plateau basaltic-rock, and Snake River Plain basaltic-rock aquifer systems in the West. The least susceptible aquifers were the Texas Coastal Uplands and Denver Basin aquifer systems.

Relatively large intraaquifer variability in redox-age classes was observed in some of the principal aquifers. For the five networks of domestic wells sampled in the Floridan aquifer system, for example, the percentage of samples classified as oxic-potentially young ranged from 10 to 100 percent. Aquifer confinement probably is an important control on redox-age variability in the Floridan aquifer system. The Central glacial aquifers also showed large redox-age variability, which could be attributed to the diversity of depositional environments represented by well networks in those aquifers.

Principal-aquifer lithology groups with the largest percentage of domestic-well networks considered to have a high susceptibility to changes in nitrate concentrations were the basaltic- and other volcanic-rock aquifer systems, carbonate-rock aquifers, and crystalline-rock aquifers. These three lithology groups include five of the six domestic-well networks with 100 percent of their samples classified as oxic-potentially young. The lithology groups with the smallest percentage of networks considered to have a high susceptibility to changes in nitrate concentrations were the glacial aquifers and sandstone aquifers. These two lithology groups include the three well networks with 0 percent of their samples classified as oxic-potentially young. There are important geologic differences between the aquifer lithology groups with high and low susceptibilities to changes in nitrate concentrations. The relatively large percentage of highsusceptibililty networks in the basaltic- and other volcanic-rock aquifer systems, carbonate-rock aquifers, and crystalline-rock aquifers may indicate the importance of fractures and karst features in promoting the rapid movement of oxic-potentially young groundwater in those aquifers. The relatively small percentage of high-susceptibility networks in the glacial and sandstone aquifers reflects geologic characteristics of those aquifers that support anoxic redox conditions (high electron donor content) and inhibit water movement (fine-grained confining layers).

Domestic-well networks in the eastern and western United States differed with respect to the percentage of samples assigned to certain redox-age classes. The 45 networks located in the western United States had a larger median percentage (13 percent) of samples classified as oxic-potentially old than the 60 networks located in the East (4 percent). Previous studies already noted the presence of oxic groundwater that was sometimes thousands of years old in organiccarbon-poor unconsolidated sand and gravel aquifers in the western United States, particularly in the Central Valley and Rio Grande aquifer systems, and the Basin and Range basinfill and High Plains aquifers. Those aquifers typically have low natural recharge rates and large, thick flow systems. In contrast, networks located in the eastern United States had a larger median percentage (20 percent) of samples classified as anoxic-potentially young than networks located in the West (7 percent). This is not surprising considering the generally shallower depths to water, higher natural recharge rates, and smaller, shallower flow systems in the eastern United States than in the West. Oxic-potentially old and anoxic-potentially young conditions both reduce aquifer susceptibility to changes in nitrate concentrations, but for different climatic, geologic, and hydrologic reasons.

Fifteen of the domestic-well networks were approximately collocated with networks of shallow monitoring wells in agricultural areas, which provided the opportunity to compare the susceptibility to changes in nitrate concentrations at different depths in the same aquifer area. The median depth of the domestic wells was greater than the median depth of the monitoring wells for each pair of well networks. For 10 of the 15 pairs of networks, the monitoring-well networks had the higher percentage of samples classified as oxic-potentially young, indicating that susceptibility tended to be higher at the shallower depths of the monitoring wells.

For the parts of aquifers that provide public water supplies, the aquifers most susceptible to changes in nitrate concentrations were the Eastern glacial aquifers and the California Coastal Basin, Basin and Range basin-fill, and High Plains aquifers in the West. The least susceptible aquifer was the Cambrian-Ordovician aquifer system in the upper Midwest.

Only four of the networks of public-supply wells were approximately collocated with networks of domestic wells. The median depth of the public-supply wells was greater than the median depth of the domestic wells for each pair of well networks. For three of the four pairs of networks, the publicsupply wells had the higher percentage of samples classified as oxic-potentially young, indicating that susceptibility tended to be higher in the vicinity of public-supply wells than in the vicinity of domestic wells even though the public-supply wells had larger median well depths. Although the number of paired networks of public-supply and domestic wells was small, this finding is the opposite of what was observed for shallow monitoring wells and domestic wells. Previous studies found that high rates of pumping in public-supply wells with long screens induced more rapid downward movement of young groundwater than did domestic wells, which had shorter screens and were less heavily pumped. The data from this study are generally consistent with those findings.
