AN ANALYSIS OF THE PRESSURE RISE IN SEALED MAGAZINE FIRES

Howard R. Baum

Abstract

A mathematical model for the pressure and temperature rise in sealed ship magazines caused by propellant fires is developed. The model is a simplified version of several existing zone fire models, modified to consider sealed compartments. The equations describing the model are solved exactly. Sample results are shown for a variety of magazine geometries.

1. INTRODUCTION

A propellant fire in a sealed magazine possesses two features not present in most building compartment fires. First, the propellant contains its own oxidizer, permitting the fire to be maintained even in the absence of an adequate supply of room air. Second, the magazine is sealed with a structure designed to resist large pressure differences between the internal and external environments. As a result, a large pressure rise can occur in a magazine fire, unlike most building compartment fires. Although adequate computer models for closed building compartments [1], as well as more general building environments [2,3] exist, their tacit assumption of a limited pressure rise prevents their use for the present investigation. However, in most respects, the mathematical model presented below is really nothing more than a greatly simplified version of what is already implemented in these codes. The additional simplifying assumptions permit exact analytical solutions to be obtained for the pressure and temperature histories in the magazine. These solutions permit the sensitivity of the results to the various

thermophysical and geometric parameters which describe the problem to be readily assessed. They should be of some interest in their own right as there are few, if any, other exact solutions to the compartment fire equations.

2. MATHEMATICAL MODEL

The magazine is assumed to be a closed rectangular volume of height H and plan area A . The propellant fire is represented by a source of heat of constant strength Q . At any instant of time t the flow pattern consists of a buoyant plume feeding heat and mass into a uniformly mixed hot upper layer of temperature $T(t)$. Beneath the hot upper layer is a cold layer of gas assumed to be at the ambient temperature T_o . The plume entrains mass from the lower layer causing the interface height $Z(t)$ to descend towards the floor. The pressure $P(t)$ is the same everywhere in the magazine at each instant of time. The theoretical and experimental justification for this picture is analyzed by Quintiere [4].

In order to predict the evolution of the mean pressure, temperature, and interface height with time, it is necessary to consider mass and energy balances in the enclosure. Let ρ_u and ρ_L be the gas densities in the upper and lower layers, respectively. Then, using the perfect gas equation of state, these quantities can be rewritten as:

$$\rho_u = \frac{P(t)}{RT(t)} ; \rho_L = \frac{P(t)}{RT_o} \quad (1)$$

Here R is the gas constant. Since the room is sealed, and the propellant mass is much smaller than the room air mass, the total mass of gas in the room can

be taken as constant. Thus, if P_0 is the initial ambient pressure:

$$P \left\{ \frac{(H-Z)}{T} + \frac{Z}{T_0} \right\} = \frac{P_0 H}{T_0} \quad (2)$$

Next consider the mass flow into the upper layer. If $\dot{m}(Z)$ is the mass flux entrained into the buoyant plume at a height Z above the source, then a mass balance in the upper layer yields

$$\frac{d}{dt} \left\{ \frac{AP}{RT} (H-Z) \right\} = \dot{m}(Z). \quad (3)$$

Cetegen, et al. [5] proposed a simple empirical formula for \dot{m} based on a comparison of the point source plume theory with a variety of experimental data. In the present notation:

$$\dot{m}(Z) = 0.21 \rho_L \sqrt{gZ} Z^2 \{ Q / \rho_L C_p T_0 \sqrt{gZ} Z^2 \}^{1/3} \quad (4)$$

Here, g is the gravitational acceleration and C_p the specific heat at constant pressure.

Finally, consider an energy balance for the entire magazine. The internal energy per unit volume is $P(t)/(\gamma-1)$, where γ is the specific heat ratio in the gas. Since the chamber is sealed with immovable walls, the first law of thermodynamics can be written for the whole enclosure in the form:

$$\frac{d}{dt} \left\{ \frac{AHP(t)}{(\gamma-1)} \right\} = (1-\chi) Q - q_c A \quad (5)$$

The first term on the right hand side of eq. (5) is the rate at which heat is released into the magazine. A fraction χ of the total chemical heat release rate Q is radiated out of the gas. The second term represents the convective heat lost to the ceiling and walls in the upper layer. The quantity q_c is the convective heat flux per unit area, and it is assumed to be related to the temperature rise above the ambient ceiling temperature by a heat transfer coefficient h as follows:

$$q_c = h (T(t) - T_o) \quad (6)$$

Equations (1)-(6) constitute the mathematical system to be solved. It must be supplemented by initial conditions for the interface height $Z(t)$ and pressure $P(t)$. The natural choice is

$$Z(0) = H \quad (7)$$

$$P(0) = P_o$$

The initial temperature cannot be specified but must be determined as part of the solution. This situation arises because a steady-state plume model is used in the analysis which delivers hot gas to the ceiling in zero time. Mathematically, the system is equivalent to a second order system of differential equations, which can only support two initial conditions.

2.1 Solution

Using eq. (2) to eliminate the temperature, the mathematical problem can be reduced to the solution of the following pair of differential equations for $P(t)$ and $Z(t)$.

$$\frac{1}{\gamma-1} \frac{dP}{dt} + \frac{hT_o (P - P_o)}{P_o H - PZ} = \frac{Q_o (1 - \chi)}{AH}$$

$$\frac{d}{dt} (PZ) = - \frac{0.21}{A} gQ \frac{\gamma-1}{\gamma}^{1/3} (PZ)^{2/3} Z$$
(8)

Now introduce non-dimensional variables $\hat{P}(\tau)$ and $\hat{Z}(\tau)$ in the form

$$P = P_o \hat{P}(\tau)$$

$$Z = H \hat{Z}(\tau)$$
(9)

$$t = \frac{P_o^{1/3}}{gQH^2} A \tau.$$

Equations (7) and (8) then can be rewritten as:

$$\frac{d\hat{P}}{d\tau} + \Delta \frac{(\hat{P} - 1)}{(1 - \hat{P}\hat{Z})} = q$$

$$\frac{d}{d\tau} (\hat{P}\hat{Z}) = - \alpha (\hat{Z}\hat{P})^{5/3} / \hat{P}$$

$$\alpha = 0.21 \frac{\gamma-1}{\gamma}^{1/3}$$
(10)

$$\Delta = \frac{(\gamma-1)hT_o A}{H(gQH^2 P_o^2)^{1/3}}$$

$$q = (1-\chi) \frac{(\gamma-1)}{H} \frac{Q}{\sqrt{g} P_0 H}^{2/3}$$

$$\hat{P}(0) = \hat{Z}(0) = 1$$

Rather than work with \hat{P} and \hat{Z} directly, it is more convenient to use \hat{P} and a new variable x , defined by:

$$x \equiv (\hat{Z}\hat{P})^{-1/3} \quad (11)$$

Then, dividing the first of eqs. (10) by the second:

$$\frac{d\hat{P}}{dx} = \frac{3\hat{P}x}{\alpha} \quad q - \frac{x^3}{x^3 - 1} \Delta(\hat{P} - 1)$$

$$\text{at } x = 1; \hat{P} = 1 \quad (12)$$

Once eq. (12) has been solved, the dimensionless time τ can be recovered by using the second of eqs. (10).

$$\tau = \frac{3}{\alpha} \int_1^x ds s \hat{P}(s) \quad (13)$$

Equation (13) also shows that the domain of interest for x is given by

$$1 \leq x \leq \infty.$$

The initial value problem defined by eq. (12) can be readily solved by noting that the equation, though non-linear, is of the Ricatti type. Thus, writing $\hat{P}(x)$ in the form

$$\hat{P}(x) = f(x) \frac{d\phi}{dx} / \phi$$

(14)

$$f(x) = \frac{\alpha}{3\Delta} (x^3 - 1)/x^4$$

leads to the following linear differential equation for ϕ

$$\frac{d^2\phi}{dx^2} = \frac{3xq}{\alpha} - \frac{f'}{f} + \frac{37d}{\alpha} \frac{x^4}{x^3 - 1} \frac{d\phi}{dx} \quad (15)$$

This can be immediately integrated once to yield:

$$\frac{d\phi}{dx} = [a/f(x)] \exp\{3qx^2/2\alpha + \int_1^x dt/f(t)\} \quad (16)$$

Integrating eq. (16) by parts then yields the general expression for ϕ .

$$\phi = a \left\{ \exp[u(x)] - \int_1^x dt (3qt/\alpha) \exp[u(t)] + b \right\} \quad (17)$$

$$u(x) = 3qx^2/2\alpha + \int_1^x dt/f(t)$$

Using eqs. (16) and (17) in the recipe for $\hat{P}(x)$ given by eq. (14), and evaluating the constant b from the initial condition given in eq. (12), the final expression for $\hat{P}(x)$ becomes:

$$\frac{P}{P_0} \equiv \hat{P}(x) = 1 - \frac{3q}{\alpha} [k(x)]^{-1} \int_1^x ds s k(s)^{-1} \quad (18)$$

$$k(x) = \frac{x-1}{\sqrt{x^2+x+1}} \Delta/\alpha \exp \left\{ 3(\Delta+q)x^2/2\alpha + \frac{\sqrt{3}\Delta}{\alpha} \arctan \frac{2x+1}{\sqrt{3}} \right\}$$

For convenience, the remainder of the solution can be summarized as a function of x as follows:

$$\hat{Z} \equiv \frac{Z}{H} = [\hat{P}(x) x^3]^{-1}$$

$$(\theta) \equiv \frac{T}{T_0} = 1 + x^3 (\hat{P} - 1)/(x^3 - 1) \quad (19)$$

$$\tau = \frac{3}{\alpha} \int_1^x ds s \hat{P}(s)$$

Note that eqs. (18) and (19) constitute the exact solution to eqs. (10) for any values of the three parameters α , Δ , and q . Thus, if a somewhat different formulation of the model were adopted, with different physical constants of defining α , Δ , and q , eqs. (18) and (19) would still apply. Finally, the initial value for the temperature can be extracted from this solution. Since small τ corresponds to x near 1; from eq. (18) for $x-1 \ll 1$:

$$\hat{P}(x) \approx 1 - 3q (x-1)/(\Delta+\alpha)$$

Substituting this result into the second of eqs. (19); the desired result is obtained:

$$\theta(0) \equiv \frac{T}{T_0} (0) = \frac{1+q}{\Delta+\alpha} \quad (20)$$

3. RESULTS AND DISCUSSION

The above solution was applied to study the pressure and temperature rise induced by a 33.3 MW propellant fire in four compartments whose planform geometry is defined in table 1. Each compartment was 3.05 m in height.

Table 1
Summary of Magazine Planform Configurations

<u>Configuration</u>	<u>Planform Dimensions (Meters)</u>
1	4.57 x 4.57
2	9.15 x 12.2
3	9.78 x 14.6
4	12.2 x 24.4

The results are shown in figs. 1-4. Each figure consists of three parts, showing the time evolution for the first ten seconds of the interface height, pressure, and upper layer temperature in each compartment. Three curves are shown for each quantity, corresponding to differing estimates of the fraction χ of the chemical heat released lost to the boundaries by radiation. These curves should be treated as empirical calibration curves, to be used in conjunction with experimental data as it becomes available to determine the "best fit" value of χ . For this purpose, the remaining physical parameters were held fixed at values given in table 2.

Table 2
Summary of Reference Values for Physical Parameters
Used in Figures 1-4

<u>Quantity</u>	<u>Value</u>
Pressure P_0	1 Atm = 1.013×10^5 PA
Temperature T_0	293 K
Heat Transfer Coef. h	28.4 W/m ² K
Specific Heat Ratio γ	1.4
Gravitational Acceleration g	9.81 m/sec ²

The results indicate a substantial pressure rise in all cases, compared with the situation usually encountered in compartment fires. Indeed, only the heavily reinforced nature of the construction of the magazine permits such pressures to be achieved without rupturing the walls. In the case of configuration 1, it might not be possible to prevent rupture of the compartment walls if the upper end of the calculated range of pressures proves correct. Further work using the more detailed models listed in the references, but modified to account for hermetically or near hermetically sealed-type enclosures, is clearly needed. The present model can ultimately be most useful as a test case against which to check modified versions of the computer codes that implement the more general models.

4. ACKNOWLEDGMENTS

The author and his colleagues are grateful to Dr. Warren Jaul and Dr. Kent Farmer of the Navy Weapons Center for several discussions which provided a great deal of useful background information about the problem addressed in this report.
